

INFORMATION TO USERS

This manuscript has been reproduced from the microfilm master. UMI films the text directly from the original or copy submitted. Thus, some thesis and dissertation copies are in typewriter face, while others may be from any type of computer printer.

The quality of this reproduction is dependent upon the quality of the copy submitted. Broken or indistinct print, colored or poor quality illustrations and photographs, print bleedthrough, substandard margins, and improper alignment can adversely affect reproduction.

In the unlikely event that the author did not send UMI a complete manuscript and there are missing pages, these will be noted. Also, if unauthorized copyright material had to be removed, a note will indicate the deletion.

Oversize materials (e.g., maps, drawings, charts) are reproduced by sectioning the original, beginning at the upper left-hand corner and continuing from left to right in equal sections with small overlaps. Each original is also photographed in one exposure and is included in reduced form at the back of the book.

Photographs included in the original manuscript have been reproduced xerographically in this copy. Higher quality 6" x 9" black and white photographic prints are available for any photographs or illustrations appearing in this copy for an additional charge. Contact UMI directly to order.

ACKNOWLEDGMENTS

Thank you is long overdue to all who have had a stake in this project. Without their combined support this study could not have been brought to completion.

My thanks are extended to each member of my Dissertation Committee. Although he was unable to see this study finished, I am deeply indebted to the late Dr. Royce Ronning who acted as emeritus co-chairperson of my Committee until the time of his death. Dr. Ronning supervised and supported me through the protocol analysis study upon which this study is based, and through proposal writing of the present study. I am equally grateful to my current chair Dr. David Moshman who has advised me since I first arrived at UNL more years ago than either of us cares to remember. Dave's consistent and kind support helped me clarify my focus and communicate my ideas in a reasonably coherent manner. To members Dr. Barbara Plake who guided me through data analysis, Dr. Ken Kiewra who spent considerable time critiquing an earlier draft of this report, and Dr. Ross Thompson who was supportive and facilitating in bringing this project to closure, thank you.

My colleagues and friends--Nancy Fieber, Marlene Mahoney, Kathy Hoffman and Cindy Hromek--spent countless hours of what would have been leisure time to achieve acceptable coder reliability for the study and to

collectively score more than 200 instruments and verbal protocols. Each of them truly owns a share in this report.

Thank you my friends, I owe each one of you. I am indebted as well to the many nurse colleagues and students who either participated as subjects or who helped recruit subjects for the study (many did both). Their interest in my work truly made this project possible.

My five children--John (who made countless trips home to try to teach me the subtle ways of Word Perfect), Chris, LeLe, Pete and Jen--are, and always will be, my most prized accomplishments. Over the course of my graduate education, and too often in spite of it, they have grown to become productive, creative, value-conscious adults. They have supported me every step of the way and I hope I've made them proud.

CHAPTER I

INTRODUCTION

The practice of nursing requires ongoing assessment of clients' changing conditions, interpretation of data, determination of appropriate nursing actions and evaluation of outcomes. In short, nursing requires expertise in identifying and solving problems. Even newly graduated nurses can expect to be involved in solving complex clinical problems. It follows that nurse educators must prepare graduates who have well practiced problem solving skills.

Many nursing instructors assume that students interpret, organize and apply facts in the same manner in which they are presented in lectures and texts. Those instructors do not consider how students rely upon prior knowledge and experiences to organize and interpret newly acquired information.

Conventional testing methods such as multiple choice or short answer tests, offer little enlightenment to instructors relative to how students think through their responses to clinical problems. Conventional methods very often fail to identify the frameworks used by students to

understand and organize their tasks, or reveal the cognitive steps that produce various solutions.

Given that students organize and process information in unique ways, educators must have a means to identify those cognitive differences so that meaningful teaching methods can be matched to students' performance levels. To date, no efficient method exists in nursing education to assess components of ongoing student problem solving behavior.

The Research Problem

A number of studies involving clinical problem solving in nursing have been conducted. Work by Benner (1983, 1984), Benner and Tanner (1987) and Tanner (1988) exemplifies a major thrust in nursing of the phenomenological perspective of novice to expert cognitive skill acquisition proposed by Dreyfus and Dreyfus (1986). The processes underlying expertise, according to the Dreyfus viewpoint, are beyond adequate explanation by mechanistic or rationalist methods and therefore, cannot be reduced to computer models as is often done in information processing studies. Because the Dreyfus Theory cannot explain behavior of experts it appears to offer little toward design of objective, diagnostic or instructional methods capable of

moving novice nurses toward better methods in making clinical judgements.

An alternative may be found in a theory developed by J. R. Anderson (1982; 1983; 1986; 1987) called the Adaptive Control of Thought, or ACT* (pronounced Act-Star) Theory of Cognitive Skill Acquisition. The Theory specifies stage-like mechanisms by which novices become experts. Verbal protocols collected from novice and expert nurses in an earlier study were consistent with the three cognitive processing stages described in the ACT* Theory (Hartley & Ronning, 1987).

ACT* Theory Stage Level Behavior

Stage one of skill learning in ACT* is the declarative (novice) stage. Learners in this stage have little or no organized knowledge specific to a problem. They use a piecemeal approach and general purpose problem solving strategies to interpret perceived data. Novices, for example, student nurses first encountering a patient with insulin shock, are often unable to retain the information obtained about the problem situation while they search long term memory (LTM) for possible meaning and associations. When connections are found, they often lead to dead ends. Because novices lack specific content knowledge, they rely

on common knowledge to form inferences or analogies that associate isolated facts and/or interpretations into some kind of meaningful solution. In the case of the patient with insulin shock, the novice, missing or ignoring refuting evidence, might infer that the patient is intoxicated because his behavior fits a stored memory of intoxication.

In stage two, the compilation (intermediate) stage, solvers acquire small stores of specific content knowledge (like facts about diabetes) and learn, through classroom and textbook examples, to use simple, nondiscriminant rules to solve basic problems related to that content. When a solver must interpret the meaning of events in an actual situation, memory is at first heavily relied upon to find and retrieve rules that specify the interpretation of each bit of information. Repeated successes in solving similar types of problems however, result in the elimination of step-by-step memory search. Instead, several steps, noted by the solver to have worked in solving the class of problems, begin to occur as a smooth coordinated set. For example, the intermediate level nursing student will be able to use clinical assessment rules to interpret most of a patient's observed signs and symptoms and group them into meaningful clusters (e.g., vital signs), obtain and use patient history

and assessment findings to select a likely diagnostic category (diabetes) and retrieve/match basic stored information (signs of coma versus shock) to the actual situation. Discriminating contextual information embedded in complex problems will be overlooked by this level solver due to lack of experience needed to form additions and exceptions to general clinical rules.

Experts, those who have reached the procedural stage (stage three), rapidly identify the critical elements of a problem. What they perceive triggers automatic application of an organized set of cognitive responses that are specified in memory as the conditional actions to take when specific situational/contextual conditions are present. Because experts initially characterize problems outside conscious awareness, processing capacity is free to interpret subtle contextual information that differentiates complex problems. Increasing levels of expertise are achieved in this manner (Anderson, 1982; 1983; 1987). To continue the above example, an expert nurse knowing a patient is diabetic, will immediately isolate the critical signs that differentiate coma from shock, and then validate the match by explaining causation based upon the context in

which the patient is found, for example, the third trimester of pregnancy.

Although ACT* provides a useful framework to identify information processing differences in learners, it is impractical to collect protocol data, traditionally used for information processing analyses, in classrooms. Additionally, analysis procedures are time consuming, dependent upon error-free transcriptions and reliability of trained coders.

Prompted by similar constraints, Rest and others constructed a paper-pencil instrument with fixed-choice, stage-related items, to document subjects' interpretations of Kolberg's moral dilemmas (Rest, 1975; Rest, Cooper, Coder et al., 1974). The instrument was able to reflect stage shifts in subjects' response patterns that were consistent with their written justifications scored according to Kolberg's scoring rules. There is, then, a precedent for proposing that a paper-pencil instrument can be used to identify stage-like patterns in clinical problem solvers.

Purposes of the Study

The purpose of the proposed study was to assess reliability and validity of a nine item, fixed-choice/open-ended instrument: The Cognitive Process Self

Report (CPSR). This instrument was constructed by the investigator to assess cognitive skill stage level in nurses. A secondary purpose of the study was to contribute to the construct validity of the ACT* Theory used here as the theoretical basis of the CPSR development. Related purposes were to determine if identified differences in problem solving of student/nurse subjects were related to differences in subjects' initial interpretations of a problem and to subjects' reported levels of clinical knowledge and experience.

Significance of the Study

Investigators in other fields such as chess, physics, social studies and medicine have documented the presence of qualitatively different problem solving patterns among solvers with different levels of experience (deGroot, 1966; Larkin, 1983; Larkin, McDermott, Simon & Simon, 1980; Lesgold, 1984; Lesgold, Feltovich, Glaser & Wang, 1981; Voss, Tyler & Yengo, 1983). Studies in the area of nursing have more recently begun to address the issue. Verbal protocols have been analyzed by nurse investigators to obtain categorical group data about clinical problem solving (Kerr, 1987; Tanner, Padric, Westfall & Putzier, 1987).

Little attention, however, has been given to applying theory from cognitive psychology to research findings.

Presently, outcome measures in nursing education are being stressed by accrediting bodies. Given this trend, availability of a reliable paper-pencil method to assess information processing at different stages in a student's career is of practical significance. Once identified, changing patterns in the student's abilities to organize and process information can be matched to stage-appropriate teaching methods to help reach desired outcomes.

Research Questions

The specific questions addressed in this study were:

1. Can adequate measures of reliability be established for the Cognitive Process Self-Report (CPSR)?
2. Is there evidence of a positive relationship between the levels used to classify subjects on the CPSR and subjects' levels of clinical experience?
3. Do the nine items on the CPSR individually and collectively identify subgroup differences in reported cognitive actions that are consistent with stage-related, goal-directed cognitive actions described by Anderson (1982, 1983, 1987)?

4. Is there a relationship between subjects' level of problem representation and their cognitive skill level classification on the CPSR?
